# **Chapter 1**

# **The Linear Approximation Table**

We will define the **Linear Approximation Table**  $\mathcal{L}$  of any S-Box. We abbreviate "linear approximation table" by **LAT**.

Suppose we are given a S-Box S takes n-bit sequences to m-bit sequences. The LAT S of S is a table (or matrix) with  $2^n$ -rows and  $2^m$ -columns. The entries of the LAT  $\mathcal{L}$  consist of integers. This includes both positive and negative integers,m as well as zero.

#### 1.1 Motivation

We calculate the LAT's of the S-Box's used in given block cipher as the first step in designing an attack on that block cipher by linear cryptanalysis.

How does the LAT of a S-Box reveal potential vulnerabilities of a block cipher that uses it in its design?

If the LAT of a S-box contain some "large" integer value (either positive or negative) then a block cipher that uses that S-Box may be vulnerable to an attack by linear cryptanalysis.

# 1.2 Preliminaries

#### 1.2.1 The Filed of Two Elements

Define  $\mathbb{F}_2 = \{0, 1\}$  to be the filed of two elements. We interpret  $\mathbb{F}_2$  as the set of bits (zero and one). We have two binary operation on  $\mathbb{F}_2$  namely **addition** and **multiplication**, so that  $\mathbb{F}_2$  becomes a **field** under these operations.

• 
$$\oplus$$
 :  $\mathbb{F}_2 \times \mathbb{F}_2 \to \mathbb{F}_2$ .

- The **addition operation** on *F*<sub>2</sub> is the logical operator XOR.
- It is denoted by  $\oplus$ .

$\boldsymbol{x}$	y	$x \oplus y$
0	0	0
0	1	1
1	0	1
1	1	0

• &: 
$$\mathbb{F}_2 \times \mathbb{F}_2 \to \mathbb{F}_2$$
.

- The **multiplication operation** on  $F_2$  is the logical operator AND.
- It is denoted by ⊙.

х	y	$x \odot y (xy)$
0	0	0
0	1	0
1	0	0
1	1	1

#### 1.2.2 Sequences of Bits

By a sequence of bits, we mean a sequence of 0's and 1's. Define  $\mathbb{F}_2^n$  to be the st of bit sequences of length n, where n is a positive integer.

$$\mathbb{F}_2^n = \left\{ (x_1, \dots, x_n) : x_i \in \mathbb{F}_2 \right\}.$$

- $\mathbb{F}_2^n$  has  $2^n$  elements.
- $\mathbb{F}_2^n$  is in bijection with the set of integers  $\{0, 1, \dots, 2^n 1\}$ .

#### 1.2.3 The Dot Product

We can define the **dot product** operation, which is a map from  $\mathbb{F}_2^n \times \mathbb{F}_2^n$  to  $\mathbb{F}_2$ . That is,

$$\bullet: \mathbb{F}_2^n \times \mathbb{F}_2^n \to \mathbb{F}_2.$$

We define dot product  $x \cdot y \in \mathbb{F}_2$  by

$$x \cdot y = \bigoplus_{i=1}^{n} x_i y_i,$$

where  $x = (x_1, \ldots, x_n)$  and  $y = (y_1, \ldots, y_n)$  in  $\mathbb{F}_2^n$ .

An expression that we will encounter in defining the linear approximation table is:

$$(a \cdot x) \oplus (\beta \cdot y).$$

Here  $\alpha, x \in \mathbb{F}_2^n$  and  $\beta, y \in \mathbb{F}_2^m$ . Then

$$\begin{cases} \alpha \cdot x \in \mathbb{F}_2 \\ \beta \cdot y \in \mathbb{F}_2 \end{cases} \implies (a \cdot x) \oplus (\beta \cdot y) \in \mathbb{F}_2.$$

## 1.3 Definition of a S-Box

#### S-BOX

**Definition 1.1.** Let  $n, m \in \mathbb{Z}^+$  be positive integers. Let

$$S: \mathbb{F}_2^n \to \mathbb{F}_2^m$$

be any function. We call *S* a **S-BOX**. Note that *n* and *m* represent the number of **input bits outputs bits**, respectively.

## 1.4 Linear Equations Associated to a S-Box

Let  $S: \mathbb{F}_2^n \to \mathbb{F}_2^m$  be a given S-Box with n input bits and m output bits. Suppose  $\alpha = (\alpha_1, \ldots, \alpha_n) \in \mathbb{F}_2^n$  and  $\beta = (\beta_1, \ldots, \beta_m) \in \mathbb{F}_2^m$  are given. We are interested in solutions  $x \in \mathbb{F}_2^n$  of the equation:

$$(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0.$$

We call  $\alpha$  and  $\beta$  the **masks** of the equation.  $\alpha$  is the **input mask** and  $\beta$  is the **output mask**. We can write

$$S(x) = S(x_1, ..., x_n) = y = (y_1, ..., y_m)$$

where  $x_1, ..., x_n \in \mathbb{F}_2$  are the **input variables** and  $y_1, ..., y_m \in \mathbb{F}_2$  are the **output variables**. Note that  $y_i$  are not free variables but rather are determined by the choice of the free variables  $x_i$ .

Then the equation  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$  can be written as:

$$\left(\bigoplus_{i=1}^{n} \alpha_{i} x_{i}\right) \oplus \left(\bigoplus_{j=1}^{m} \beta_{j} y_{j}\right) = (\alpha_{1} x_{1} \oplus \cdots \oplus \alpha_{n} x_{n}) \oplus (\beta_{1} y_{1} \oplus \cdots \oplus \beta_{m} y_{m}) = 0.$$

This is a **linear equation** of the input variables  $x_1, \ldots, x_n$  and the output variables  $y_1, \ldots, y_m$ . Let  $S : \mathbb{F}_2^n \to \mathbb{F}_2^m$  be a S-Box. For  $\alpha \in \mathbb{F}_2^n$  and  $\beta \in \mathbb{F}_2^m$ , we define the set  $\Sigma_{\alpha,\beta}$  by:

$$\Sigma_{\alpha,\beta} = \left\{ x \in \mathbb{F}_2^n : (\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0 \right\}.$$

So,  $\Sigma_{\alpha,\beta}$  is the set of all values  $x \in \mathbb{F}_2^n$  that satisfy the linear equation:  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$ . We also define the non-negative integer  $e_{\alpha,\beta}$  to be the cardinality of the set  $\Sigma_{\alpha,\beta}$ , namely:

$$e_{\alpha,\beta} = |\Sigma_{\alpha,\beta}|$$
.

Since  $\Sigma_{\alpha,\beta}$  is a subset of  $\mathbb{F}_2^n$ , and the cardinality of  $\mathbb{F}_2^n$  is  $2^n$ , we get rough bound on  $e_{\alpha,\beta}$ 

$$0 \le e_{\alpha,\beta} \le 2^n$$
.

# 1.5 Bias and Probability

In general if p is a **probability** of an event then p is a real number between 0 and 1, that is  $0 \le p \le 1$ . From a given probability we can define an associated quantity called the **bias**, usually denoted  $\epsilon$ .

#### Bias

**Definition 1.2.** The bias  $\epsilon$  is defined in terms of the probability p by the formula

$$\epsilon = p - \frac{1}{2}$$
.

Therefore, the bias is a real number in the range  $-\frac{1}{2} \le \epsilon \le \frac{1}{2}$ .

So, a bias can be negative whereas a probability can not. Conversely, if we are given the bias  $\epsilon$  then the associated probability p is given by

$$p=\epsilon+\frac{1}{2}.$$

Just as p=0 and p=1 are the edge cases of a probability value, the values  $\epsilon=-\frac{1}{2}$  and  $\epsilon=\frac{1}{2}$  are the edge cases of a bias value.

Note that a probability of  $p = \frac{1}{2}$  has a bias of  $\epsilon = 0$ . So, for example on the toss of a fair coin, both heads and tails have a bias 0.

# 1.6 Linear Equations and Bias

Given  $\alpha \in \mathbb{F}_2^n$  and  $\beta \in \mathbb{F}_2^m$  we have defined number of  $x \in \mathbb{F}_2^n$  which satisfy the equation  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$  to be  $e_{\alpha,\beta} = |\Sigma_{\alpha,\beta}|$ . Therefore, the probability of  $x \in \mathbb{F}_2^n$  satisfying the equation  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$  is:

$$p_{\alpha,\beta} = \frac{\left|\Sigma_{\alpha,\beta}\right|}{\left|\mathbb{F}_2^n\right|} = \frac{e_{\alpha,\beta}}{2^n}.$$

As with all probabilities we have  $0 \le p_{\alpha,\beta} \le 1$ .

So, the **bias** of the equation  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$  holding is:

$$\epsilon_{\alpha,\beta} = p_{\alpha,\beta} - \frac{1}{2}.$$

Since  $p_{\alpha,\beta} = \frac{e_{\alpha,\beta}}{2^n}$  we can write the bias as

$$\epsilon_{\alpha,\beta} = \frac{e_{\alpha,\beta}}{2^n} - \frac{1}{2} = \frac{e_{\alpha,\beta} - 2^{n-1}}{2^n}.$$

We call the numerator of this expression the **bias integer** associated to  $\alpha$  and  $\beta$  and denote it as:

$$e'_{\alpha,\beta} = e_{\alpha,\beta} - 2^{n-1}$$
.

Recall that  $0 \le e_{\alpha,\beta} \le 2^n$ . Subtracting  $2^{n-1}$  from this inequality gives:

$$0 \le e_{\alpha,\beta} \le 2^{n}$$

$$0 - 2^{n-1} \le e_{\alpha,\beta} - 2^{n-1} \le 2^{n} - 2^{n-1}$$

$$-2^{n-1} \le e_{\alpha,\beta} - 2^{n-1} \le 2^{n} (1 - 2^{-1})$$

$$-2^{n-1} \le e_{\alpha,\beta} - 2^{n-1} \le 2^{n-1}.$$

Which gives us rough bounds for the possible values of the **bias integer**  $e'_{\alpha,\beta}$ 

$$-2^{n-1} \le e'_{\alpha,\beta} \le 2^{n-1}$$
.

By definition, the bias is obtained from the bias integer by dividing it by  $2^n$ :

$$\epsilon_{\alpha,\beta} = \frac{e'(\alpha,\beta)}{2^n}.$$

#### 1.7 The LAT of a S-Box

#### The Linear Approximation Table (LAT)

**Definition 1.3.** Let  $S : \mathbb{F}_2^n \to \mathbb{F}_2^m$  be a S-Box. The **linear approximation table** (abbreviated **LAT**) of S is a table of integers with  $2^n$ -rows and  $2^m$ -columns. We denote it by  $\mathcal{L}$ .

- The rows are indexed by the elements  $\alpha \in \mathbb{F}_2^n = \{0, \dots, 2^n 1\}$ .
- The columns are indexed by the elements  $\beta \in \mathbb{F}_2^m = \{0, \dots, 2^m 1\}$ .
- The entry at row index  $\alpha$  and column index  $\beta$  is given by the bias integer  $e'_{\alpha,\beta}$ .

$$\mathcal{L} = (e'_{\alpha,\beta}).$$

So, the LAT of a S-Box is just a table of all possible bias integer  $e'_{\alpha,\beta}$ .

**Note.** The linear approximation table  $\mathcal{L}$  of a S-Box  $S : \mathbb{F}_2^n \to \mathbb{F}_2^m$ :

$\mathcal{L}$	0	1	• • •	β	• • •	$2^{m}-1$
0	$2^{n-1}$					
1	0					
:						
$\alpha$	0			$e'_{\alpha,\beta}$		
:				71		
$2^{n}-1$	0					

We will see that for any LAT the first column is all zeros except the first entry which is  $2^{n-1}$ .

# 1.8 Properties of the LAT

We already proved that the entries  $e'_{\alpha,\beta}$  of the LAT are integers between  $-2^{n-1}$  and  $2^{n-1}$ . Consider the case  $\alpha=0$  and  $\beta=0$ . Then every  $x\in\mathbb{F}_2^n$  is a solution to  $(\alpha\cdot x)\oplus(\beta\cdot S(x))=0$ . Therefore,  $\Sigma_{0,0}=\mathbb{F}_2^n$  and so  $e_{0,0}=\left|\mathbb{F}_2^n\right|=2^n$ . The corresponding bias integer is

$$e'_{0,0} = e_{0,0} - 2^{n-1} = 2^n - 2^{n-1} = 2^{n-1}$$
.

So, for any LAT, the value in the upper-left corner is always  $2^{n-1}$ .

**Lemma 1.1.** Let  $\alpha \in \mathbb{F}_2^n$  with  $\alpha \neq 0$  and n > 1. Define the following subset of  $\mathbb{F}_2^n$ :

$$W = \left\{ x \in \mathbb{F}_2^n : \alpha \cdot x = 0 \right\}.$$

Then the cardinality of W is  $2^{n-1}$ .

*Proof.* Since  $\alpha = (\alpha_1, \dots, \alpha_n) \neq 0$ ,

$$\exists i_0 \in \{1, \ldots, n\} : \alpha_{i_0} \neq 0.$$

Assume that  $i_0 = 1$ . We can write

$$\alpha = (1, \alpha')$$
 where  $\alpha' \in \mathbb{F}_2^{n-1}$ .

Define a map

$$\phi : \mathbb{F}_2^{n-1} \longrightarrow W \\ x \longmapsto (\alpha' \cdot x, x) .$$

Note that  $\phi$  is well defined since

$$\alpha \cdot \phi(x) = \alpha \cdot (\alpha' \cdot x, x) = (\alpha' \cdot x) \oplus (\alpha' \cdot x) = 0.$$

Since  $\phi$  is bijection, the cardinality of W equals that of  $\mathbb{F}_2^{n-1}$ , which is  $2^{n-1}$ .

Let us consider the values of the first column of the LAT (except for the first entry). This corresponds to the case  $\alpha \neq 0$  and  $\beta = 0$ . The equation  $(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0$  becomes  $\alpha \cdot x = 0$ . By the previous lemma the cardinality of the set of  $x \in \mathbb{F}_2^n$  satisfying  $\alpha \cdot x = 0$  is  $2^{n-1}$ . Hence  $e_{\alpha,0} = 2^{n-1}$ . And so,

$$e'_{q,0} - 2^{n-1} = 2^{n-1} - 2^{n-1} = 0.$$

So, the first column of any LAT has its first entry as  $2^{n-1}$  and then all zeros below that. This case where  $\beta = 0$  is not of interest in applications since it does not involve the S-Box S.

Suppose *S* is a bijection (one-to-one and onto). Then necessarily n = m. So.

$$S: \mathbb{F}_2^n \to \mathbb{F}_2^n \quad \text{and} S^{-1}: \mathbb{F}_2^n \to \mathbb{F}_2^n.$$

Suppose  $x \in \mathbb{F}_2^n$  and let  $y = S(x) \in \mathbb{F}_2^n$ . Then  $x = S^{-1}(y)$ . Then

$$(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0 \equiv (\beta \cdot y) \oplus (\alpha \cdot S^{-1}(y)) = 0.$$

This shows that for any  $\alpha$  and  $\beta$ , we have  $e_{\alpha,\beta}^S = e_{\beta,\alpha}^{S^{-1}}$ . Hence:

$$\mathcal{L}_{S^{-1}} = (\mathcal{L}_S)^T.$$

This says the LAT of  $S^{-1}$  is the transpose of the LAT of S. Therefore, when S is a bijection the first row and the first column are all zeros, except for the upper-left entry which is  $2^{n-1}$ .

**Proposition 1.2.** If  $S : \mathbb{F}_2^n \to \mathbb{F}_2^n$  is a bijective S-Box and n > 1 then the entries of the LAT are all even integers.

Proof.

# 1.9 Complexity

Note that there are  $2^n$  possible choices of  $\alpha$  and  $2^m$  possible choices of  $\beta$ . Therefore, there are  $2^n \cdot 2^m = 2^{n+m}$  possible equations:

$$(\alpha \cdot x) \oplus (\beta \cdot S(x)) = 0.$$

There are  $2^n$  possible inputs  $x \in \mathbb{F}_2^n$  to each equation. So, to calculate the LAT of a S-Box will require  $2^{n+m} \cdot 2^n = 2^{2n+m}$  calculations.

For example if n = m = 8 this gives  $2^{3n} = 2^{3 \cdot 8} = 2^{24} = 16,777,216$  possibilities to look at (which is no problem computationally).

## 1.10 Coding the LAT

#### 1.10.1 Dot Product

```
1
   int dot(int u, int v) {
2
       int w = u \& v;
3
       int dot = 0;
4
       // Using Kernighan's algorithm to count the number of set bits
5
       while (w) {
6
7
           dot ^= 1;
8
           w &= w - 1; // clear the least significant bit set
9
10
       return dot;
11
12
   }
   int main() {
13
14
       int u = 0b101010;
                            // Example binary numbers
15
       int v = 0b110100;
16
17
       // Dot product: 1
18
       printf("Dot product: %d\n", dot(u, v));
19
20
       return 0;
21
22
   }
```

```
1 // S is a list of integers that gives the values of the S-Box
  // n = number of input bits of the S-Box S
  // alpha is the input mask
  // beta is the output mask
  int bias_integer(int S[], int alpha, int beta, int n) {
5
       int e = 0;
6
       int range = 1 << n; // 2 ** n</pre>
7
8
       for (int x = 0; x < range; x++) {
9
10
           if (dot(alpha, x) \wedge dot(beta, S[x]) == 0) {
11
               e++;
12
           }
       }
13
14
       return e - (range >> 1); // range / 2 or 2 ** (n - 1)
15
16 }
17
  int main() {
18
19
       // Example S-box (replace with actual values)
       int S[] = \{1, 2, 3, 4, 5, 6, 7, 8\};
20

```

# 1.11 S-Box Analysis

**Note** (**Parity Bits**). Parity bits are a simple, yet powerful, method of error detection in digital communications and data storage. A parity bit is a bit that is added to a group of source bits to ensure that the number of set bits (i.e., bits with value 1) is even or odd. There are two types of parity bits:

- Even Parity: The parity bit is set so that the total number of 1-bits in the code is even.
- **Odd Parity**: The parity bit is set so that the total number of 1-bits in the code is odd.

The calculation of a parity bit depends on the desired parity (even or odd). For a given set of bits, the process is as follows:

- 1. Count the number of bits set to 1 in the data.
- 2. For even parity, if the count is odd, set the parity bit to 1. If the count is even, set the parity bit to 0.
- 3. For odd parity, if the count is even, set the parity bit to 1. If the count is odd, set the parity bit to 0.

Parity bits are widely used in various forms of data transmission and storage to detect errors. They are particularly useful in detecting single-bit errors.

While parity bits can detect single-bit errors, they are not capable of detecting all types of errors, such as two-bit errors or the exact location of the error. Parity bits are a simple, yet powerful, method of error detection in digital communications and data storage. A parity bit is a bit that is added to a group of source bits to ensure that the number of set bits (i.e., bits with value 1) is even or odd.

```
int parity(int n) {
1
2
       int count = 0;
3
       while (n) {
4
           count ^= n & 1;
5
           n >>= 1;
6
       }
7
       return count;
8
  }
```

## Example 1.1. Consider

$$u8 s_box[8] = \{0x7, 0x0, 0x6, 0x4, 0x5, 0x2, 0x1, 0x3\};$$

That is,

$$000 \mapsto 111$$
 $001 \mapsto 000$ 
 $010 \mapsto 110$ 
 $011 \mapsto 100$ 
 $100 \mapsto 101$ 
 $101 \mapsto 010$ 
 $110 \mapsto 001$ 
 $111 \mapsto 011$ .

Let S(1, 1, 0) = (0, 0, 1) where

$$x_2 = 1$$
,  $x_1 = 1$ ,  $x_0 = 0$ ,  $y_2 = 0$ ,  $y_1 = 0$ ,  $y_0 = 1$ .

$$x_2 + x_1 + x_0 = y_2 + y_1 + y_0$$

# **Chapter 2**

# **Linear Cryptanalysis**

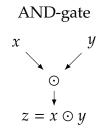

#### **Overview**

- Proposed by Matsui[Mat93]
- Broke DES with 2<sup>47</sup> known plaintext-ciphertext pairs
- One of two major statistical attack techniques and design criteria for block ciphers (and other primitives)
- Main idea:
  - 1. Find approximate equation about XOR of selected bits  $M_i$ ,  $C_i$  and  $K_i$ .
  - 2. Use equation as distinguisher to recover the key

# 2.1 Linear Approximations and Characteristics

"Finding paths through the cipher"

#### Approximating non-linear functions by linear functions

Inj	put	Output	Linear Functions					
$\boldsymbol{x}$	y	$z = x \odot y$	0	x	y	$x \oplus y$		
0	0	0	0	0	0	0		
0	1	0	0	0	1	1		
1	0	0	0	1	0	1		
1	1	1	0	1	1	0		
	Pro	bability	$\frac{3}{4}$	$\frac{3}{4}$	$\frac{3}{4}$	$\frac{1}{4}$		

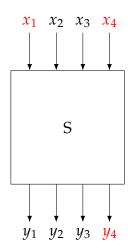

We get four different equally efficient approximations for  $z = x \odot y$  that are correct with probability  $\frac{3}{4}$ :

$$z \approx 0$$
,  $z \approx x$ ,  $z \approx y$ ,  $z \approx x \oplus y \oplus 1$ .

# Linear Approximation of S-Boxes

**Example 2.1.** An output bit of the PRESENT S-Box:

x	0	1	2	3	4	5	6	7	8	9	A	В	С	D	Е	F
S(x)	С	5	6	В	9	0	A	D	3	Е	F	8	4	7	1	2

$x_1$	$x_2$	$x_3$	$x_4$	$y_1$	$y_2$	<i>y</i> <sub>3</sub>	$y_4$	$y_4 = x_1 \oplus x_4$
0	0	0	0	1	1	0	0	✓
0	0	0	1	0	1	0	1	✓
0	0	1	0	0	1	1	0	✓
0	0	1	1	1	0	1	1	✓
0	1	0	0	1	0	0	1	×
0	1	0	1	0	0	0	0	×
0	1	1	0	1	0	1	0	✓
0	1	1	1	1	1	0	1	✓
1	0	0	0	0	0	1	1	✓
1	0	0	1	1	1	1	0	✓
1	0	1	0	1	1	1	1	✓
1	0	1	1	1	0	0	0	✓
1	1	0	0	0	1	0	0	×
1	1	0	1	0	1	1	1	×
1	1	1	0	0	0	0	1	✓
1	1	1	1	0	0	1	0	✓
								1

#### Linear Masks

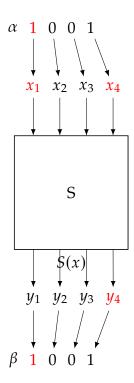

- We are interested in any linear equation of n input and n output bits.
- Select bits with **masks**  $\alpha$ ,  $\beta \in \mathbb{F}_2^n$  and the **inner product**

$$\alpha \cdot x := \bigoplus_{i=1}^n (\alpha_i \odot x_i).$$

Alternative notion:  $\alpha \cdot x^T$  or  $\langle \alpha, x \rangle$  or  $\ell_{\alpha}(x)$ 

• Linear approximation:

$$\alpha \cdot x = \beta \cdot S(x).$$

#### Measuring the Quality of the Approximation: Bias & co.

- The quality of the approximation  $(\alpha, \beta)$  of the n-bit S-Box S can be desribed equivalently using the following metrics:
  - Solutions

$$e_{\alpha,\beta} = \# \Sigma_{\alpha,\beta} = \# \left\{ x \in \mathbb{F}_2^n : \alpha \cdot x = \beta \cdot S(x) \right\}$$

- Probability

$$p = \mathbb{P}_x \left[ \alpha \cdot x = \beta \cdot S(x) \right] = \frac{e_{\alpha,\beta}}{2^n}$$

- Bias

$$\epsilon = p - \frac{1}{2}$$

- Correlation

$$\eta_{\epsilon} = 2 \cdot \epsilon$$
.

• For  $y_4 = x_1 \oplus x_4$ , we have

$$e_{\alpha,\beta} = 12$$
 
$$p = \frac{12}{16}$$
 
$$\epsilon = \frac{12}{16} - 1 = \frac{1}{4}$$
 
$$\eta_{\epsilon} = 2 \cdot \frac{1}{4} = 2^{-1}.$$

- Assume we have a linear approximation  $\alpha \cdot x = \beta \cdot S(x)$  that holds with bias  $\epsilon$ :
  - If  $\epsilon = 0$ , we learn nothing (as good as random guess, correct half the time)
  - If  $\epsilon > 0$ , the approximation  $\alpha \cdot x = \beta \cdot S(x)$  is good
  - If  $\epsilon$  < 0, the approximation  $\alpha \cdot x = \beta \cdot S(x) \oplus 1$  is good

# 2.2 Linear Approximations of (Affine) Linear Functions

Consider a linear function (e.g., part of the diffusion layer)

$$y = \mathcal{L}(x)$$
.

Then any approximation is either perfect ( $\eta_{\epsilon} = \pm 1$ ) or useless ( $\eta_{\epsilon} = 0$ ). Which approximations ( $\alpha, \beta$ ) are good?

Write  $\mathcal{L}$  as a matrix multiplication  $y = \mathcal{L} = L \cdot x$ , then

$$\eta_{\epsilon}(\alpha, \beta) = \begin{cases} 1 & : \alpha = L^T \cdot \beta \\ 0 & : \text{else.} \end{cases}$$

If  $\mathcal{L}$  is affine linear (linear function  $\oplus$  constant), the correlation may be  $\pm 1$ , depending on the constant. In particular, the key addition in a key-alternating cipher may change sign  $\pm 1$ .

Key Addition + S-Box

Linear Approximation:

$$(\alpha \cdot x) \oplus (\kappa \cdot k) = \beta \cdot y.$$

Then

$$x_1 \oplus x_4 \oplus k_1 \oplus k_4 = y_4$$
 or  $x_1 \oplus x_4 \oplus y_4 = k_1 \oplus k_4$ 

1-bit equation about the key!

Key Addition + S-Box + Key Addition + S-Box

Linear Approximation:

$$\begin{cases} (\alpha \cdot x) \oplus (\kappa \cdot k) = \beta \cdot y \\ x_1 \oplus x_4 \oplus k_1 \oplus k_4 = y_4 \end{cases} \quad \text{and} \quad \begin{cases} (\beta \cdot y) \oplus (\kappa' \cdot k') = \gamma \cdot z \\ y_4 \oplus k'_4 = z_2 \oplus z_4 \end{cases}$$

implies

$$\begin{cases} (\alpha \cdot x) \oplus (\kappa \cdot k) \oplus (\kappa' \cdot k') = \gamma \cdot z \\ x_1 \oplus x_4 \oplus k_1 \oplus k_4 \oplus k'_4 = z_2 \oplus z_4 \end{cases}$$

What's the Bias of this Approximation?

The two approximations hold with probabilities

$$p_1 = \frac{1}{2} + \epsilon_1 = \frac{1}{2} + \frac{4}{16} = \frac{3}{4},$$

$$p_2 = \frac{1}{2} + \epsilon_2 = \frac{1}{2} - \frac{4}{16} = \frac{1}{4}.$$

The combined approximation is correct if both are correct or both are wrong; so, assuming the two probabilities are independent:

$$p = p_{1} \cdot p_{2} + (1 - p_{1}) \cdot (1 - p_{2})$$

$$= 2 \cdot p_{1} \cdot p_{2} - p_{1} - p_{2} + 1$$

$$= 2 \cdot \left(\frac{1}{2} + \epsilon_{1}\right) \cdot \left(\frac{1}{2} + \epsilon_{2}\right) - \left(\frac{1}{2} + \epsilon_{1}\right) - \left(\frac{1}{2} + \epsilon_{2}\right) + 1$$

$$= \frac{1}{2} + 2 \cdot \epsilon_{1} \cdot \epsilon_{2}.$$

## Piling-up Lemma

**Lemma 2.1.** Let  $X_i$   $(1 \le i \le n)$  be independent Boolean expressions (corresponding to the individual approximations) with probabilities  $p_i = \Pr[X_i = 0] = \frac{1}{2} + \epsilon_i$ . Then

$$\Pr[X_1 \oplus X_2 \oplus \cdots \oplus X_n = 0] = \frac{1}{2} + 2^{n-1} \prod_{i=1}^n \epsilon_i.$$

*Or in terms of the correlation*  $\eta_{\epsilon} = 2 \cdot \epsilon$ :

$$\eta = \prod_{i=1}^n \eta_i.$$
